Abstract: Recent developments in optical biosensors based on integrated photonic devices are reviewed with a special emphasis on silicon-on-insulator ring resonators. The review is mainly devoted to the following aspects: (1) Principles of sensing mechanism, (2) sensor design, (3) biofunctionalization procedures for specific molecule detection and (4) system integration and measurement set-ups. The inherent challenges of implementing photonics-based biosensors to meet specific requirements of applications in medicine, food analysis, and environmental monitoring are discussed.

Keywords: biosensors; biophotonics; integrated optical sensors; aptamers; biomaterials; optical sensor; silicon photonics; ring resonators; lab-on-a-chip

1. Introduction

Silicon-based photonic biosensors integrated into a semiconductor chip technology can lead to major advances in point-of-care applications, food diagnostics, and environmental monitoring through the rapid and precise analysis of various substances. In recent years, there has been an increasing interest in sensors based on photonic integrated circuits (PIC) because they give rise to cost effective, scalable and reliable on-chip biosensors for a broad market \([1,2]\).

The silicon-on-insulator (SOI)-technology is the most attractive technology for PICs since it provides a scalable platform for mass production \([3,4]\) and the opportunity for monolithic integration of electronic and photonic devices, which is known as electronic photonic integrated circuits (EPIC) \([5]\). This allows the integration of sensors, detectors, light-sources and read-out electronics in a single chip \([6–10]\).

Once the photonic chip is fabricated, the silicon surface of the sensor can be coated with a covalently attached sensing layer \([11]\). This layer determines the specific detection and, hence, the application. This step, however, is independent from the fabrication of the chip, making the SOI-technology attractive for both, science and industry. A further advantage of SOI-based biosensors is the possibility to realize sensor arrays. This allows for the detection of several substances in parallel (multiplexing) \([12]\).

The SOI-based photonic biosensor can be realized by using interferometric or resonant structures. The former one is usually based on a Mach-Zehnder interferometer \([13]\) configuration and the later most often on a ring resonator \([14]\). Mach-Zehnder interferometer have a higher temperature stability compared to ring resonators but suffer from high sensitivity \([15–17]\). Ring resonators, however, have the advantage over Mach-Zehnder interferometer of a high sensitivity and small footprint, which allows for a dense sensor-integration \([18]\). It is notable that, beside aforementioned SOI-based...
sensors, plasmonic sensors have gained increasing research interest [19–21]. Those sensors were demonstrated to achieve extraordinary high sensitivity but have the disadvantage to be not yet compatible with complementary metal-oxide semiconductor (CMOS)-based microelectronics for a direct readout.

Competitive traditional biosensing techniques that are already commercially used are, for example, enzyme-linked immunosorbent assay (ELISA) [22], electrochemical sensor [23], bilayer lipid membranes (BLM) [24], high performance liquid chromatography (HPLC) [25,26], micro-electrode immunoassay [27], field immunoassay [28] and surface plasmon resonance spectroscopy (SPR) [29,30]. Compared to those traditional benchtop electrochemical instruments, the main advantages of SOI-based ring resonators are their small size, scalable mass-production and fast readout (real-time) as well as the possibility for low cost, portable devices for point-of-care applications since they rely on CMOS-compatible processes.

In this work, we focus on SOI-based ring resonators and provide in the first part an overview of the working principle and sensing mechanism. The detection limits and integration challenges are critically discussed. In the second part, we review recent advances on surface functionalization and report on the detection of various biomarkers. Finally, we discuss typical experimental set-ups and recent developments regarding integration approaches.

2. Photonic Devices and Sensing Mechanisms

This section provides an introduction to photonic biosensors based on SOI ring resonators and to the underlying sensing mechanism. Furthermore, we discuss recent advances in device design and operation principles.

Operation Principle

This work is focusing on photonic sensors based on optical ring resonators in a SOI-technology. A ring resonator is composed of a silicon-based waveguide on top of a buried oxide substrate. In general, the light of a tunable laser or a superluminescentdiode is coupled to the waveguide via grating coupler or by butt coupling. The light is then partly coupled to the ring resonator if the resonance condition is fulfilled leading to resonance peaks at the output spectrum, as illustrated in Figure 1a. At the output, the light is coupled to a photodetector or an optical spectrum analyzer depending on the light source. Current advances in heterogeneous as well as monolithically integration give rise to implement laser [31,32] and photodiodes [33] on the same chip together with the photonic sensors.

![Figure 1. (a) Schematic representation of a silicon-on-insulator ring resonator. According to the resonance condition, only selected wavelengths can propagate in the ring and distinct resonance peaks appear in the output spectrum. Typical ring diameter d range from 20 µm to 100 µm. (b) Molecular binding takes place if a sample of the analyte gets in touch with the adsorbed layer on top of the silicon waveguide leading to a resonance wavelength shift Δλ.](image-url)

After the fabrication of the chip, the surface of the silicon ring resonator is functionalized with an adsorbed layer for specific detection [34]. Here, the natural silicone oxide layer on top of the silicon waveguide is advantageously used. Molecular binding takes place if a sample of the analyte gets in
touch with the adsorbed layer on top of the silicon waveguide. This results in a resonance wavelength shift, as shown in Figure 1b.

However, the general sensing mechanism underlying their operation is evanescent field sensing. If the evanescent field is altered due to an immobilization of analytes on the silicon waveguide, the resonance condition of the ring resonator is changed leading to a resonance wavelength shift. In this way, antibodies that only attach to their corresponding antigens are detected with high specificity by detecting either the resonance peak shift $\Delta \lambda$ or the intensity change $\Delta I$ (see Figure 1b). Typical operation wavelengths are within the optical O-band ($\lambda = 1310$ nm) in the optical C-band ($\lambda = 1550$ nm) because silicon is highly transparent at these wavelengths. A second reason is that these wavelengths are widely used in telecommunication applications and, therefore, many low-cost laser sources are available [35,36]. Once the analyte-antibody binding took place, the residuals can be removed by drying or flushing to enhance the specific measurement. The wavelength shift can be calculated from resonator metrics that appear in [37]

$$\Delta \lambda = \frac{\lambda_{\text{res}}}{n_g} \Delta n_{\text{clad}},$$

where $n_g$ is the group index, $\lambda_{\text{res}}$ is the resonance wavelength and $\Delta n_{\text{clad}}$ determines the refractive index change of the cladding material. The group index can be calculated by

$$n_g = n_{\text{eff}} - \frac{\lambda}{F SR} \frac{\delta n_{\text{eff}}}{\delta \lambda}.$$  

Here, the effective refractive index of the optical waveguide is denoted as $n_{\text{eff}}$. The second term of Equation (2) is referred to as dispersion of the group index. Assuming a small resonance wavelength shift and, hence, a flat dispersion, the group index can be approximated by

$$n_g \approx n_{\text{eff}} = \frac{\lambda^2}{FSR \ L_{\text{ring}}},$$

where $L_{\text{ring}}$ is the ring circumference and $FSR$ is the free spectral range.

The most important component of all integrated photonic biosensors is the silicon waveguide. During the last decade, many effort has been undertaken to improve waveguide geometries for optical sensing by simulation studies [38–40]. In principle, there are three types of widely used waveguides, namely strip waveguide, rib waveguide and slot waveguide, as illustrated in Figure 2. The evanescent field of the guided mode is partially penetrating into the cladding material, where the analyte is located. The amount of light penetrating into the cladding is different for each waveguide configuration and correlates with unwanted optical losses; i.e., the more light is penetrating into the cladding the higher the optical losses due to absorption and scattering. For example, the light is mainly confined inside the silicon core in case of a strip waveguide but in case of slot waveguides the light can be significantly confined in the vicinity of two silicon rails, as illustrated in Figure 3.

![Figure 2. Typical silicon-on-insulator waveguide geometries for optical biosensing.](image-url)
Depending on the application, it is necessary to choose an appropriate waveguide type. Rib waveguides show low optical losses at the cost of sensitivity. In contrast, slot waveguides exhibit a large sensitivity but high optical loss at the same time. Strip waveguides, in contrast, offer a good compromise between loss and sensitivity, as illustrated in Figure 2. As a rule of thumb, the more light is interacting with the analyte the higher is the waveguide sensitivity but the optical losses are increased, too. From Figure 3 it is apparent that the highest optical field confinement in the cladding is provided by the slot waveguide structure. Simulation studies have revealed that SOI slot waveguides achieve an optical field confinement of 0.7, i.e., 70% of the guided light is confined in the cladding and not in the silicon core [39–41]. In contrast, strip waveguides achieve an optical field confinement factor of 0.2. Another important parameter is the polarization state of the light, which is usually either transverse-electric (TE) or transverse-magnetic (TM). Most often, the guided light is TE-polarized in SOI-based PIC because it provides less optical losses. On the other hand, TM-polarized light can lead to an increased sensitivity since it has a higher field overlap with the cladding material, where the analyte is located. However, TE-polarized light is presumed in this work, except something else is specified. A comprehensive design guideline to choose the most appropriated waveguide type for a specific application can be found in Refs. [42,43]. To improve the sensor performance in terms of sensitivity, it is useful to distinguish between the waveguide sensitivity and the ring resonator sensitivity. The former describes the interaction of the guided light with the surrounding medium. It takes into account that the effective refractive index is altered if the cladding refractive index is changed. The waveguide sensitivity is given by

$$S_{wg} = \frac{\Delta n_{eff}}{\Delta n_{clad}}, \quad (4)$$

where $\Delta n_{eff}$ represents the effective refractive index change. Such a definition is useful for waveguide optimization through simulation studies. However, the ring resonator sensitivity depends not only on the waveguide geometry and, therefore, a second definition defining the ring resonator sensitivity is given by

$$S_{rr} = \frac{\Delta \lambda}{\Delta n_{eff}}. \quad (5)$$

Taken both definitions into account, we get the overall photonic device sensitivity defined by

$$S = S_{wg}S_{rr} = \frac{\Delta n_{eff}}{\Delta n_{clad}} \frac{\Delta \lambda}{\Delta n_{eff}} = \frac{\Delta \lambda}{\Delta n_{clad}}. \quad (6)$$

Please note that the unit of this definition is often written as $nm/RIU$, where $RIU$ denotes the refractive index unit. It should be noted that the change of the cladding refractive index $\Delta n_{clad}$ is
induced by binding of antigens to the functionalized waveguide surface. These definitions, however, are solely related to the photonic device and not to a directly measurable quantity. In this scenario, the minimum detectable change in the cladding refractive index gives us the limit of detection (LOD), which depends clearly on the minimum detectable resonance wavelength shift $\Delta \lambda_{\text{min}}$ that can be resolved by the measurement set-up. For example, an optical spectrum analyzer has a typical wavelength resolution of 20 pm. This measurement resolution ($MR$) can be determined by

$$MR = \Delta \lambda_{\text{min}}.$$ (7)

This leads to the LOD given by

$$\text{LOD} = \frac{\Delta \lambda_{\text{min}}}{S}.$$ (8)

To get a metric which is independently from the measurement set-up, an intrinsic LOD ($iLOD$) is necessary [44]. It can be obtained by setting the measurement resolution $MR$ as full width at half maximum ($FWHM$) of the resonance peak, which leads to

$$iLOD = \frac{FWHM}{S} = \frac{\lambda_{\text{res}}}{QS},$$ (9)

where $Q$ denotes the optical quality factor, which is determined by

$$Q = \frac{\lambda_{\text{res}}}{FWHM}.$$ (10)

Finally, we provide a strategy to improve the waveguide geometry by design. Towards this, we consider the most important characteristics of integrated photonic biosensors, which can be divided into five categories [14]:

1. Increasing the waveguide sensitivity $S_{\text{wg}}$ increases the light-analyte-interaction. In fact, this determines the wavelength shift $\Delta \lambda$ and has a strong impact on the overall sensitivity.

2. Enhancing the ring resonator sensitivity $S_{\text{rr}}$, which determines the wavelength shift $\Delta \lambda$ depending on the refractive index change $\Delta n_{\text{eff}}$. This can be achieved by increasing the light-matter interaction using slot waveguide structures.

3. A small $FWHM$, i.e., a high Q-factor, impacts the sensitivity of ring resonator sensors since the impact of noise on the determination of the resonance wavelength will be reduced [45,46]. A higher Q-factor leads to a lower attenuation in the ring and minimizes the smallest detectable wavelength shift $\Delta \lambda$ and consequently the detection limit.

4. A small footprint is directly related to the detection time and reduces the area consumption and therefore device costs significantly. Furthermore, this allows a high integration density, which is of special interest for multiplexing.

5. Compatibility with a semiconductor production platform, which gives the ability for an industrial production flow. The compatibility with an electronic-photonic integrated circuit (EPIC) allows for a monolithic integration.

As mentioned before, each waveguide-type has advantages and disadvantages and therefore, a design trade-off regarding sensitivity and optical losses is necessary. Recently, a hybrid-waveguide ring resonator was proposed to combine a strip waveguide with a slot waveguide in such a way that the figure of merit $FOM = \frac{S_{\text{rr}}}{FWHM}$ is maximized [14]. Figure 4 shows a schematic representation of this SOI ring resonator, which consists of both a strip waveguide and a slot waveguide [47–50]. This type of ring resonator has been demonstrated to have an improved figure of merit compared to more common strip or slot waveguide-based ring resonators, as it is summarized in Table 1.
A comparative study on the sensor performance of slot and strip waveguide ring resonators is given in Ref. [51]. Here, glucose level monitoring in blood samples in the range 10 to 200 mg/dL using minimal invasive technique is simulated. Additionally, a six times higher $S_{rr}$ of the slot waveguide ring resonator is estimated using the Finite Element Method (FEM).

In 2009, a novel sensing approach were introduced by Daoxin Dai [52]. He proposed to cascade two micro-rings in such a way that it works analogously to a Vernier-scale. Claes et al. [53] have demonstrated this principle by using micro-rings with large circumferences to make it work in another regime that allows to reduce the detection limit. This method were several times adopted and highly sensitive biosensors were demonstrated that exceed the sensitivity of more common single-ring sensors [54–56].

It is also notable that advances on planar silicon ring resonators with novel guiding structures have been theoretically investigated. Such resonator structures show ring resonator sensitivities of up to 120 nm/RIU and high Q-factors of $10^5$ [58], which could result in a record high $FOM$ of about 7742. More recently, polarization independent slot waveguide structures were theoretically demonstrated to double the waveguide sensitivity [59]. More recently, in 2019, sub-wavelength grating (SWG) waveguides have been demonstrated to exhibit a sensitivity of 1900 pm/nm [60]. These results show the potential for integrated high sensitive optical biosensors in a SOI technology and give prospective to further improvements.

3. Functionalization Procedures and Applications

In this section we give a basic introduction of to label-free functionalization procedures and a short overview of recent advances in the bio-functionalization of photonic sensors based on SOI-technology.
The aim of current research on SOI ring resonators is to improve their sensitivity in order to make them cost effective through the integration in highly scalable production flows and to realize real-time indication of biomolecules and toxins with high reliability and is currently focused primarily to medical diagnostics. Rapid and simple diagnostics of acute inflammation, for example, can support the decision for the correct medicine to provide primary medical care inside and outside of hospitals as well as to monitor therapeutic interventions.

For experimental development antibody-antigen model systems like anti bovine serum albumin (antiBSA)-bovine serum albumin (BSA) [61] are typically used for proof of concepts. In a standard procedure (e.g., ELISA), the high specificity and affinity biotin-streptavidin biotin binding is widely used as linker. Therefore, this system is also used as model system for proof of concepts and to validate SOI ring resonators [45,62,63]. In general, the biospecific interaction is following the key-lock principle allowing for high selectivity.

Over the past 10 years, several researchers have successfully demonstrated functionalized SOI ring resonators for the detection of acute inflammations, viral diseases and cancer by biomarkers such as proteins [12,45,62], interleukins [64], nucleic acids [65,66], and viruses [67]. A brief overview is given in Table 2.

For this purpose, the silicon surface of the ring resonator has to be functionalized with the corresponding bioactive receptors. The bioactive receptors can be either covalently or adsorptively immobilized to the silicon surface.

Covalent immobilization gives a tight binding of the organic receptors on the inorganic silicon surface. As a rule, up to four reaction steps (A–D) are required for this, as shown in Figure 5 by means of an example from Ref. [72]:

1. **(A) Surface activation**
   The surface activation is carried out by cleaning the silicon surface with piranha solution or hydrogen peroxide-ammonium hydroxide solution followed by an argon plasma to generate hydroxyl groups.

2. **(B) Surface functionalization**
   To immobilize the bioactive receptors, agents like bifunctional organosilane of the general formula \( R_3-Si-(CH_2)_n-X \) with hydrolysable groups \( R \) (OCH\(_3\), CH\(_2\)CH\(_3\), Cl, F, SH) are often used, for example, (3-Aminopropyl)triethoxysilane (APTES) (in Figure 5). The choice of functional groups \( X \) (NH\(_2\), epoxy, SH, C=C) depends strongly on the desired specification. The condensation of these materials with the surface hydroxyl groups results in the formation of siloxane bonds (Si-O-Si). Such coupling leads to monolayers that is covalently bonded on the silicon surface and therefore highly stable.
3. **(C) Linker**

The linker molecules are also bifunctional. In some cases they are symmetrical in structure, such as the widely used amine-to-amine linker glutaraldehyde or bis (sulfosuccinimidyl) suberate (BS3), but may also carry two different functional groups, e.g., N-γ-maleimidobutyryl oxysuccinimide ester (GMBS), which is an amine-to-sulfhydryl crosslinker that contains NHS esters and maleimide reactive groups at opposite ends of a short spacer arm. In the example shown in Figure 5, a heterobifunctional crosslinker reacts with the amino-modified surfaces. In this case, a succinimidyl-6-hydrazino-nicotinamide (S-HyNic) is used as linker molecule.

4. **(D) Immobilisation of receptor**

Immobilization of biomolecules as receptors such as antibodies requires a pre-modification of those biomolecules. Thus, biotinylation can introduce functionality into the biomolecule. In the example shown in Figure 5, a 4-formylbenzamide (4FB)-modified antibody is used to form a stable covalent hydrazone linkage at the 6-hydrazinonicotinamide (HyNic) moieties.

On the one hand, this procedure allows a stable binding but, on the other hand, it requires a sophisticated synthetization, but the application justifies the effort.

In contrast, adsorptive immobilization via ionic or van der Waals interactions is easier to use, and allows for fast measurements without specific reagents and is applied despite the disadvantage of low sensitivity due to an incorrect orientation, as shown in Figure 6a. Using a protein layer, Caroselli and co-workers improved the alignment of antibody receptors [61].

However, adsorption is the weakest compound because it can be resolved by varying pH, temperature or ionic strength changes. Another problem is the possible inactivation due to the change in the 3D-structure of the biomolecule after adsorption on the sensor surface. For this reason, the covalent immobilization is preferred for highly sensitive and selective measurements.

SOI ring resonators are well suited for the detection of analytes with molecular weights in the range of kilodaltons, while molecular weights of more than megadalton (MDa) may exceed their size the evanescent field region of the sensor and lead to an invalid result [43]. However, recognition of bean pod mottle virus (7 MDa) demonstrates the principle feasibility of detecting high molecular weight molecules. For small molecules [mDa] a detectable signal is difficult to obtain from SOI-based sensors, especially at low concentrations due to low sensitivity or high noise level.
Figure 6. (a) The antibody receptors are usually randomly oriented on the silicon surface when they are directly immobilized using physical adsorption. (b) Using a protein A layer leads to properly oriented antibody receptors. Reproduced from Ref. [61] (CC BY 4.0).

One great advantage of integrated photonic biosensors is the ability for multiplexing making this technology attractive for diagnostics and interaction screening [73]. For example, Luchansky et al. have demonstrated a fast multiplexing system using 32-element arrays of ring resonators to quantify several species with excellent time-to-result [69,74]. In particular, they have detected the cytokines interleukin-2 (IL-2), interleukin-4 (IL-4), interleukin-5 (IL-5), and tumor necrosis factor alpha (TNFα) in parallel with high accuracy in serum-containing cell media.

Recent developments in antifouling coatings have led to a further reduction of nonspecific protein binding to the sensor surface. For example, Jäger et al. [75] have examined methylated dendritic polyglycerol (dPG(OMe)) as a protective layer. In this case, fibrinogen was used to test the antifouling properties. A reduction of 87% in the binding of fibrinogen to the silicon surface was demonstrated by using a SOI rib waveguide-based ring resonator.

4. System Integration

In this section we discuss different measurement set-ups used in laboratories and review current advances to integrate them into a SOI platform.

The most common set-up is shown in Figure 7. It comprises either a tunable laser source in combination with a photodiode (Figure 7a) or a broadband light source with a optical spectrum analyzer (Figure 7b). The polarization of the light is typically adjusted by a 3-paddle polarization controller. To avoid temperature fluctuations, the sample holder is heated just above room temperature. The main disadvantage of this measurement is the light coupling since it requires a precise adjustment of optical fibers.

To avoid fiber coupling, current research in SOI technology is focusing on the integration of light sources and photodiodes. While Ge-photodiodes have been successfully integrated in a SOI platform [33,76–78], the integration of laser sources is still challenging [79]. Current approaches employ wafer-to-wafer [35,80] or die-to-wafer [31,81,82] bonding.

A novel integration scheme was recently proposed [83,84]. Here, a single wavelength laser is used in combination with a monolithically integrated Ge-photodiode. To obtain the transmission peaks, the ring resonator is tuned by employing a thermal heater. Both thermal tuning of the effective refractive index and thermo-optical multiplexing is used, while an expensive tunable laser source is avoided [85]. Figure 8 shows a schematic of this set-up. Each ring resonator is individually addressed and tunable by electronic signals. The modulation signal for the ring array is provided by a sinusoidal tuning signal and a separate switching unit that divides the signal in certain time slots, which are connected to a specific ring. The modulation signal induces a thermal refractive index change and, therefore, changes the resonance condition of the ring. In this way, the transmission of each ring can be detected without the need for a tunable laser.
Figure 7. Schematic of typical measurement set-ups in laboratories. (a) The light source consists of an external cavity laser, which can tune its wavelength (tunable laser). In this case, a photodiode can be used as detector. (b) If a broad band light source (e.g., superluminescent diode) is employed, an optical spectrum analyzer is needed on the detector side.

Figure 8. Schematic of ring resonator array. Each ring is separately addressed in the electronic regime to individually measure the transmission. The sinusoidal input signal is divided in certain time slots. Adopted from Ref. [85].

Current integration issues are related to chip packaging. Since the integration of light sources, photodetectors and readout require conductive interconnects and occupy many space, a backend of line (BEOL) until five metal levels are necessary for a monolithic integration. This, on the other hand, requires a relatively deep etching procedure through the BEOL in order to release the sensing area (ring resonator). This leads to a high aspect ratio and makes surface functionalization and the implementation of micro-fluids challenging. Therefore, current integration approaches prefer a hybrid integration; i.e., the integration light source and detector unit on a separate chip. The disadvantage of this approach is the sophisticated optical interconnection between each chip such as, for example, photonic wire bonding realized by direct-write two-photon lithography [86–88]. Therefore, the system integration still requires further developments and is in the focus of current research to achieve high throughput.

5. Outlook

During the last two decades, integrated photonic sensors have been intensively studied in terms of sensitivity and reliability. However, the bottle-neck for a transfer from laboratory to industry is the
position of the sensing area, since it adjoins optical and electronical components. This prohibits a full packaging and makes the sensor handling impractical. Towards the large-scale commercialization of SOI-based ring resonator biosensors, a low-cost and scalable packaging including a micro-fluidic system is required [89]. Recent developments on CMOS-compatible epoxy chip-in-carrier processes [90] or the fan-out wafer-level packaging process [4,91–93] have been demonstrated as good candidates towards this goal. Future work, however, should focus on further improvements of wafer-level packaging but also on monolithic integration of SOI ring resonators with a laser-source, photodetector and electrical interconnects on the same chip to provide full lab-on-a-chip solution.

6. Conclusions

Biosensors based on SOI ring resonators are reviewed and discussed. The theoretical background in terms of waveguide and resonator sensitivity as well as detection limits is provided and current developments in ring resonator geometries are reviewed. Furthermore, an overview of functionalized SOI ring resonators and their applications is provided. Finally, experimental set-ups for the optical characterization are described and current integration approaches are reviewed.
