

A Broadband 110-170 GHz Stagger-Tuned Power Amplifier with 13.5-dBm P_{sat} in 130-nm SiGe

Alper Karakuzulu, *Member, IEEE*, Mohamed Hussein Eissa, *Member, IEEE*, Dietmar Kissinger, *Senior Member, IEEE*, and Andrea Malignaggi

Abstract—This letter presents a fully integrated 3-stage single-ended D-band power amplifier (PA) designed in 0.13 μm silicon-germanium (SiGe) BiCMOS technology. Several bandwidth extension techniques and matching networks are mutually exploited to maximize BW performance while assuring unconditional stability. Its measured 3-dB bandwidth covers the entire D-band (110 GHz to 170 GHz). The PA has a small signal peak gain of 21 dB at 151 GHz. Its saturated output power (P_{sat}) in the D-Band varies from 11.8 dBm to 13.9 dBm and its output referred 1-dB compression point (OP_{1dB}) from 9.2 dBm to 12.5 dBm within the D-band. The presented amplifier occupies $0.65 \times 0.47 \text{ mm}^2$ (including pads) and draws a current of 115 mA from a 3.3 V supply. To our knowledge, these performance represents the state of art in silicon technology with a minimum (P_{sat}) of 11.8 dBm and (OP_{1dB}) of 9.2 dBm covering the entire D-Band.

Index Terms—Broadband, D-band, integrated circuits (IC), millimeter-wave (mm-wave), power amplifier (PA)

I. INTRODUCTION

Emerging millimeter-wave frequency applications continue to grow thanks to the recent advancements in silicon-based semiconductor technologies. To meet increased demands for high-data-rate applications, wireless communication systems with high-order modulation schemes like QAM achieved remarkable data rates of tenths of Gbit/s in mm-wave frequencies [1]. However, larger bandwidths are required for even higher data rates. In order to achieve that, a promising solution is represented by the D-band broadband spectrum, which is considered as potential candidate for high capacity backhaul links for 5G and beyond [2] [3]. By using 16 QAM or high order modulation schemes with 60 GHz bandwidth, data rates of 100 Gbit/s or more are possible. To realize such high data rates, highly linear, high power and broadband power amplifiers need to be designed.

Advanced integrated technologies provide transistors with high f_t and f_{max} . Due to many effects as interconnect parasitics, passives' quality factors etc., designing an amplifier with both high gain and high bandwidth is still a challenge, especially at high frequencies. Various bandwidth extension techniques are employed to mitigate these drawbacks at D-Band. For instance, a SiGe power amplifier achieving 3-dB bandwidth of 24 GHz with a gain of 15 dB using a power matching technique was presented in [4]. A 110-155 GHz

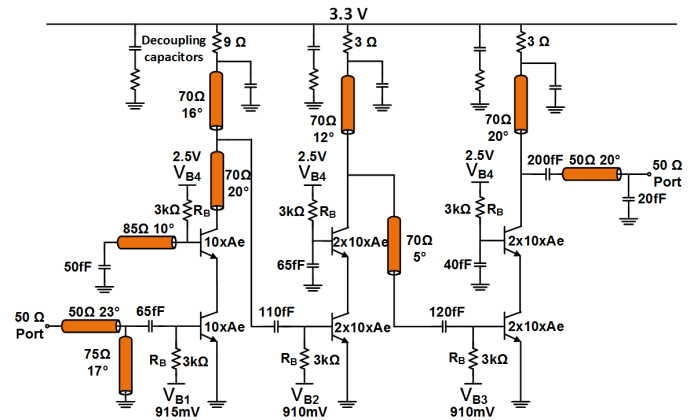

Fig. 1: Schematic of the 110 GHz to 170 GHz single-ended three-stage cascode power amplifier

PA with 10 dB gain was proposed in [5] using a broadband impedance transformation technique. High gain PAs were designed for 25 dB gain with 3-dB bandwidth of 20 GHz in [6] and 50 GHz in [7] by using T-matching and gain boosting techniques, respectively. A 100-180 GHz broadband amplifier is realized in [8]. In [9] - [11], particular interstage matching and impedance transformation techniques were used to broaden the bandwidth, achieving a 3-dB bandwidth of 35.6 GHz [9], 66.5 GHz [10], and 25 GHz [11], respectively.

In this paper, the staggered tuning technique [12] [13] for PA bandwidth extension is fully exploited and realized. In addition to that, low quality factor (Q) matching networks and gain boosting techniques are employed. The employed design techniques are implemented in a single-ended three-stage cascode amplifier. Despite the fact that the single-ended design especially at mm-wave is more prone to instability, the single-ended PA is realized to make it more efficient and small size. The PA covers entire D-band with unconditional stability.

II. CIRCUIT DESIGN

A schematic of the proposed single-ended broadband PA is shown in Fig. 1. It is designed using the IHP 0.13 μm SiGe BiCMOS technology, featuring f_t/f_{max} of 300 GHz/500 GHz. The process offers seven metal layers with two top thick metals. Top thick metal layers TM1 and TM2 are used to implement transmission lines with M3 as a ground shield.

A. The Staggered Tuning Technique

When broad bandwidth and flat frequency characteristic are targeted, tuning every stage of the multi-stage amplifier to

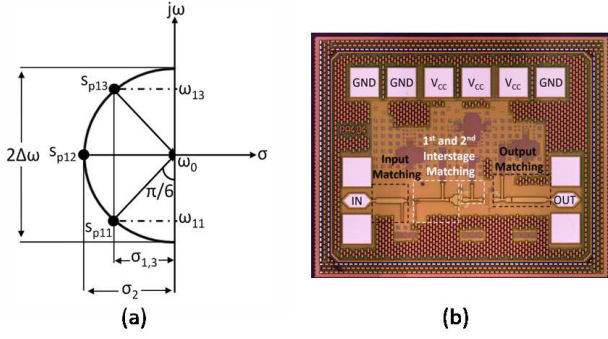

Fig. 2: (a) the pole-zero diagram of the amplifier's gain function (b) Chip micro-photograph of the three-stage PA

Fig. 3: (a) Power gain of the individual stages (b) MAG and K-factor versus frequency for the 10 fingers cascode stage with and without base transmission line

slightly different frequencies around the center frequency of the band can be a solution. To obtain the desired frequency characteristic of the multi-stage amplifier, the positions of the poles in the gain transfer function [14] were investigated. Once the number of dominant poles where resonance peaks are formed and their relative positions are known, the Q of each dominant pole can be determined defining the overall bandwidth. Since, within an amplifier as the presented one, each state contributes to a dominant pole, our analysis has to consider three dominant poles. The targeted 60 GHz bandwidth can be achieved using more than 3-stages as well. However, each additional stage will increase the power consumption and degrade the power added efficiency (PAE). In order to get a flat frequency characteristic, the Butterworth pole-zero distribution [14] is used, obtaining a gain function having the pole-zero diagram shown in Fig. 2-a. According to this diagram, the bandwidth of the 3-stage amplifier is $2\Delta\omega$ and the appropriate positions of the poles can be expressed as:

$$\sigma_2 = -\frac{\omega_0}{2Q_2}, \text{ and } \sigma_{1,3} = -\frac{\omega_{11}}{2Q_1} = -\frac{\omega_{13}}{2Q_3} \quad (1)$$

From the geometry of the pole-zero diagram, ω_{11} and ω_{13} are calculated as:

$$\omega_{11} = \omega_0 - \Delta\omega \cos\left(\frac{\pi}{6}\right) \text{ and } \omega_{13} = \omega_0 + \Delta\omega \cos\left(\frac{\pi}{6}\right) \quad (2)$$

and a magnitude of the real part of the poles can be calculated:

$$|\sigma_2| = \left|\frac{\omega_0}{2Q_2}\right| = \Delta\omega, |\sigma_{1,3}| = \left|\frac{\omega_0}{2Q_{1,3}}\right| = \frac{\Delta\omega}{2} \quad (3)$$

From (3), the Q values of each dominant pole can be extracted:

$$Q_2 = \frac{\omega_0}{2\Delta\omega} = \frac{f_0}{2\Delta f} \text{ and } Q_{1,(3)} = \frac{\omega_{11,(13)}}{2\Delta\omega} = \frac{f_{11,(13)}}{2\Delta f} \quad (4)$$

Once ω_{11} and ω_{13} are determined from (2), the Q factor of each dominant pole can be directly found from (4). The tuning frequencies of the considered amplifier are calculated as $f_{11} = 114.02$ GHz and $f_{13} = 165.98$ GHz considering a center frequency $f_0 = 140$ GHz. Using these values, knowing that the targeted bandwidth $2\Delta f$ equals 60 GHz, the Q of each stage is found to be $Q_1 = 3.8, Q_2 = 2.33$ and $Q_3 = 5.53$. Now, the interstage matching between each stage needs to be designed based on the calculated Q values. Both input and output impedances of the inter-stages are chosen for high gain (conjugate) matching. Looking at the gain circles, after few iterations optimum impedances satisfying both gain and bandwidth (Q values) requirements can be determined. The Q of the matching network is controlled and defined according to the [15] where R_L is the load and R_S is the source resistance of the matching network and for the case of $R_L > R_S$

$$Q = \sqrt{\frac{R_L}{\sqrt{R_S R_L}} - 1} \quad (5)$$

After defining tuning frequencies and Q of each stage, the gain of each stage needs to be properly determined. The basic design principle of the staggered tuning technique consists of tuning the gain of all the individual stages at different tuning frequencies in order to broaden the bandwidth of the overall transfer function. Fig. 3-a shows the simulated power gain for the different stages of the PA. Stage 1 is designed to have peak gain at 140 GHz. Considering the high frequency gain drop, stage 3, the one having minimum gain, is tuned at the low portion of the band. Besides, stage 2 is tuned around 165 GHz and a combined peak gain of stage 1 and 2 is designed to compensate the drop in gain at the higher part of the band. In addition, the maximum available gain (MAG) is increased by utilizing the gain-boosting technique with base transmission line at the first stage. The MAG has increased 2.2 dB at 140 GHz (Fig. 3-b). More importantly, the MAG of the device is becoming flatter and showing the broadband response.

B. Broadband PA Design

The broadband PA consists of three cascode stages biased in class A. The cascode topology provides high gain and good isolation between ports. Thanks to the high isolation, matching the output of a stage will not affect its input impedance. This allows designing interstage matching for pre-defined Q values without affecting previous and following stages. Optimal sizing of the transistors is important as it affects available gain, output power and input and output impedances. A transistor size which has an output impedance close to the Smith chart center is preferable to avoid an output matching network with high loss and narrow bandwidth [7]. For a linear and high power PA design, a HBT transistor of emitter area $10 \times (0.12 \times 0.9) \mu\text{m}^2$ is chosen. The HBT transistors are biased near their peak f_{max} current density at a quiescent current of 2.4 mA/Finger. Two of such transistors connected in parallel are used within the second and the third stages. These transistors are twice as big as the ones used in the first stage to be able to deliver enough power in output. The circuit has been fully EM simulated. All the matching networks

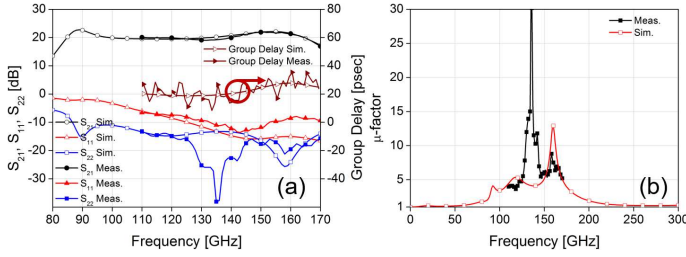

Fig. 4: Measured and simulated (a) PA s-parameters with group delay response, (b) μ -factor of the PA showing unconditional stability

Fig. 5: Measured and simulated (a) P_{out} and gain versus input power of the three-stage PA at 140 GHz (b) OP_{1dB} , PAE at P_{1dB} and P_{sat} over frequency

are implemented using transmission lines (TLs) and MIM capacitors. Inductors are implemented using transmission lines with different characteristic impedances. Input and output are matched to $50\ \Omega$ for allowing easier top level integration. Interstage nodes are matched at higher characteristic impedances to reduce matching losses and make transmission lines shorter. The gain is boosted using shunt capacitance and inductive positive feedback on the common-base stage. The first two stages are matched for maximum gain, while on the third one a load pull has been performed.

Due to the boosted gain given by the inductive positive feedback on the common-base stage, the PA could be prone to instability. Therefore, the stability check has been done with different techniques. The common ‘K-factor’ analysis may give some indication of possible instabilities; however it is not sufficient for multiple stage amplifiers [16]. K-factor analysis should be done separately for each amplifier stage [17]. For this reason, each stage is separated and both μ and K-factors are checked. Besides, s-probe analysis [18] has been done for critical nodes, especially common base nodes which could show a negative impedance. At the same time, to ensure unconditional stability at all frequencies, a small stabilization resistance is used between supply and collector of each stage to prevent any possible cross-coupling across the stages. The value of the stabilization resistor is $9\ \Omega$ for the first stage and $3\ \Omega$ for the last two stages. Furthermore, supply decoupling capacitors de-Q’ed with small resistors are integrated at the dc supply node. Fig. 4-b presents both simulated and measured μ -factor of the PA. According to the measurement results, the PA is unconditionally stable along the D-band.

III. MEASUREMENT

A. Small-Signal Measurements

The chip microphotograph of the single-ended PA is shown in Fig. 2-b. The overall size of the PA is only $0.48 \times 0.39\ \text{mm}^2$,

owing to the single-ended design. The measurement and simulation results of the small signal s-parameters are presented in Fig. 4-a. An excellent agreement for S_{21} can be seen, with a peak gain of 21.6 dB at 155 GHz. The measured 3 dB bandwidth is limited at the lower side by the measurement equipment. The measured output return loss is better than 13 dB along the D-band. Another important parameters for broadband communication applications is the group delay [19], which is measured showing variations of only $\pm 8\ \text{ps}$ across the whole band as plotted in Fig. 4-a.

B. Large-Signal Measurements

Output power (P_{out}) and gain versus input power (P_{in}) at 140 GHz are shown in Fig. 5-a. Regarding the gain measurement, the input referred 1-dB compression point (IP_{1dB}) is -8 dBm and the corresponding OP_{1dB} is 10.26 dBm at 140 GHz. To the best of authors’ knowledge, the PA shows state of the art OP_{1dB} having a minimum of 9.2 dBm across the whole D-band for Si-based PAs, with a maximum of 12.5 dBm at 151 GHz. As can be seen from the P_{out} -vs- P_{in} plot, the saturated output power at 140 GHz is 12.1 dBm. The measured and simulated OP_{1dB} and P_{sat} over the frequency are given in Fig. 5-b. The PA achieves state of the art performance showing a minimum saturated power of 11.8 dBm across the entire D-band for Si-based PAs, with a maximum of 13.9 dBm at 114 GHz. The measured power added efficiency over frequency is reported to be around 5% within the D-band. The stages show a current consumption of 23 mA, 46 mA and 46 mA respectively with 3.3 V supply voltage. The AM-PM distortion of the PA has been simulated, reaching a value of less than 1° in the linear region and 3° at P_{sat} at 140 GHz.

IV. CONCLUSION

Table I shows the performance comparison of the designed PA with other D-band amplifiers. The designed PA shows high output power performance over an outstanding broad frequency band. When compared to the state-of-the-art Si-based power amplifiers, this work shows broader bandwidth, comparable with the one showed by [8] which, on the other hand, presents 3 dB lower P_{sat} and lower efficiency. This paper presents a broadband high power D-band SiGe PA. The designed three-stage PA shows a 3-dB bandwidth from 110 GHz to 170 GHz (limited by the measurement setup). The PA achieves state of the art OP_{1dB} and P_{sat} of at least 11.8 dBm and 9.2 dBm within the entire D-band, respectively.
